Empirical Study on the Compression Rate of tiktoken for Chinese Long Texts

— Validation and Extension of the Three-Layer Quantization Framework Based on a Million-Token Dialogue

Abstract

With the widespread adoption of large-language-model (LLM) long-context capabilities, tokenizers such as tiktoken have become the de-facto standard for estimating token consumption.
Nevertheless, the internal compression behaviour of tiktoken, especially on mixed Chinese–English long texts, remains a "black box" for most practitioners. Empirical formulas (e.g., Chinese × 1.6) are widely used but have never been validated on a truly massive corpus.

In this work we leverage the DeepSeek million-token project (cleaned JSONL dialogues, 1 077 046 tokens, 3 673 rounds) and a reverse-engineering methodology to measure the real compression ratios of tiktoken on authentic Chinese long text. The main findings are:

1. The actual Chinese coefficient is ≈ 1.16, far lower than the commonly used 1.6, producing an overall token-count over-estimation of 20.9 %.
2. English, digits and "other" symbols follow the textbook coefficients (0.25, 0.5, 0.5) respectively.
3. The dialogue exhibits a clear three-stage evolution: early problem definition, a mid-stage technical-hardship period (English share ≈ 43.4 %), and a late-stage summarisation/ reflection period (Chinese share ≈ 55.2 %).
4. The average bytes per token is 2.81 B, below the usual 3.5 – 4.5 B range, likely due to the high proportion of English/code and the data-cleaning pipeline.

These results substantiate the previously proposed three-layer quantization framework and we also provide a fully reproducible calibration pipeline for other researchers.

Keywords: tiktoken; BPE tokenizer; compression rate; million-token window; empirical-formula validation; three-layer quantization framework

1. Introduction

1.1 Research background

LLMs with extended context windows (≥ 8 k tokens) are now commonplace, and the token count directly determines inference cost, latency, and feasibility of downstream tasks. tiktoken, together with other BPE-based tokenizers (e.g., sentencepiece), has become the de-facto tool for estimating that count. While the BPE algorithm is publicly documented, the effective compression ratio for Chinese characters in realistic, mixed-language corpora remains opaque—a classic "black-box" problem.

In our earlier work we introduced a three-layer quantization framework (L1 macro-ecology, L2 semantic-correction, L3 cognitive-purification) and demonstrated a "signal-to-noise" (SNR) advantage on the DeepSeek million-token project. That study used tiktoken as a standard tool but did *not* analyze its internal compression behaviour on Chinese text.

1.2 Problem statement

Practitioners often resort to a quick heuristic:

	Coefficient
Chinese characters	1.6
English characters	0.25
Digits	0.5
Other symbols	0.5

The source of these coefficients is unclear and they have never been validated on a million-token scale. Consequently we ask the following research questions (RQ):

- RQ1 – What is the actual token-per-character coefficient for Chinese in a massive mixed-language dialogue corpus?
- RQ2 – How does this coefficient compare with the standard heuristic, and what is the resulting overall bias?
- RQ3 – Does the dialogue exhibit any stage-wise evolution in language usage?
- RQ4 – Can we provide a reproducible calibration pipeline for other corpora?

1.3 Research objectives

To answer the questions above we:

1. Measure the four character-type coefficients on a genuine million-token dialogue dataset using a reverse-engineering approach.
2. Compare the measured coefficients with the standard heuristic and quantify the bias at both corpus-wide and segment-wise levels.
3. Analyse the temporal evolution of the dialogue by splitting it into three equal parts and inspecting the language-mix dynamics.
4. Release the complete analysis scripts, environment specifications and a step-by-step replication guide.

---

2. Data and Methods

2.1 Data source

We use the DeepSeek million-token project – Phase 2 (purified), released as the JSONL file QZS_Phase2_Clean_Conversations.jsonl. The data consist of turn-based *role / content* pairs. Summary statistics derived from the file are shown in Table 1.

Table 1 – Basic statistics of the cleaned dialogue corpus

Metric	Value
Total rounds (turns)	3 673
Total characters (UTF-8)	1 556 927
Total tokens (cl100k_base)	1 077 046
User rounds	1 834
Assistant rounds	1 839

All HTML markup, duplicate utterances and obvious noise were removed during the *purification* step; the remaining content is pure natural language (Chinese, English, digits and punctuation).

2.2 Methodology

All analyses were performed with Python 3.10, tiktoken 0.5.0 and the third-party regex library for Unicode-aware regular expressions.

2.2.1 Character-type classification

Four mutually exclusive categories were defined using Unicode property regexes:

Category	Regex (Python)
Chinese	[\p{Han}]

Category	Regex (Python)
English	[A-Za-z]+
Digits	\d+
Other	any remaining characters (punctuation, symbols, whitespace, full-width variants)

The classifier returns the count of characters belonging to each class for a given utterance.

2.2.2 Token counting

We employ the cl100k_base encoding (the default for OpenAI GPT-3.5/4) via:

```python
enc = tiktoken.get_encoding("cl100k_base")
len(enc.encode(text))
enc = tiktoken.get_encoding("cl100k_base")
len(enc.encode(text))
```

2.2.3 Global reverse-engineering

Let

- T = total tokens,
- C_{ch}, C_{en}, C_{di}, C_{ot} = character counts for Chinese, English, digits, other.

Assuming the *known* coefficients for the three non-Chinese categories (see §3.3.1), the Chinese coefficient a_{ch} satisfies

$$a_{ch} = \frac{T - (a_{en}C_{en} + a_{di}C_{di} + a_{ot}C_{ot})}{C_{ch}}.$$

2.2.4 Segmented analysis

The dialogue is split into three equal-size segments (first third, middle third, last third) based on the number of turns. For each segment we recompute the four character counts, token total and the corresponding a_{ch} to examine stability over time.

2.2.5 Byte-per-token verification

Under UTF-8 we approximate the average byte size of each character class:

Class	Approx. bytes per character
Chinese	3
English	1
Digits	1
Other	1.5

The estimated total bytes are

$$B = 3C_{ch} + 1C_{en} + 1C_{di} + 1.5C_{ot},$$

and the average bytes per token is B/T. This metric is compared with the typical range 3.5–4.5 bytes/token reported in the literature.

---

3. Results

3.1 Overall statistics

Table 2 summarizes character and token distributions per role.

Table 2 – Overall token and character distribution by role

Role	Turns	Characters	Tokens	Chinese % (char)	English % (char)
USER	1 834	242 442	163 238	38.1 %	33.1 %
ASSISTANT	1 839	1 314 485	913 808	42.6 %	34.7 %
TOTAL	3 673	1 556 927	1 077 046	41.9 %	34.5 %

Observations

- The assistant supplies 84.8 % of the tokens, confirming a typical "question-answer" pattern.
- Chinese and English characters are fairly balanced (≈ 42 % vs 35 %).
- Users contribute a relatively high proportion of "other" symbols (≈ 24 %), reflecting code snippets, file paths, and special symbols.

3.2 Three-stage segment statistics

Table 3 shows token counts, language-mix percentages and the USER/ASSISTANT token ratio for each third.

Table 3 – Segment-wise token and language-mix statistics

Segment	Role	Turns	Tokens	Chinese % (char)	English % (char)	Other % (char)	USER/ASSISTANT token ratio
Front 1/3	USER	611	44 179	40.4 %	27.7 %	27.2 %	1 : 5.5
	ASSISTANT	613	244 106	43.5 %	32.1 %	21.7 %	
Middle 1/3	USER	611	40 099	21.1 %	43.4 %	28.2 %	1 : 7.2
	ASSISTANT	613	290 237	30.6 %	44.5 %	22.5 %	
Back 1/3	USER	612	78 960	49.7 %	28.3 %	18.8 %	1 : 4.8
	ASSISTANT	613	379 465	55.2 %	25.8 %	15.8 %	

Three-stage evolution

Stage	Dominant characteristic	Interpretation
Front (first 1/3)	Chinese ≈ English, many user questions	Problem definition & environment setup
Middle (second 1/3)	English dominates (≈ 44 % of characters) and assistant output becomes longest	Technical-hardship period – code, configuration, deep-technical discussion
Back (last 1/3)	Chinese share rises to ≈ 55 %	Summarisation, reflection, paper-writing

The middle stage shows the highest USER/ASSISTANT token ratio (1 : 7.2) and the peak English proportion (≈ 44 %).

3.3 Reverse-engineering of coefficients

3.3.1 Measured English/Digit/Other coefficients

Using pure-English, pure-digit and pure-other subsets we obtain:

Category	Characters	Tokens per character
English	536 849	0.250
Digits	47 747	0.500
Other	319 920	0.500

These match the textbook values, justifying the assumption used for the global reverse-engineering.

3.3.2 Global Chinese coefficient

Plugging the measured non-Chinese coefficients into the formula (Section 2.2.3) yields

$$a_{ch} = \frac{1\,077\,046 - (0.25 \times 536\,849 + 0.5 \times 47\,747 + 0.5 \times 319\,920)}{652\,411} = \mathbf{1.16}.$$

Thus each Chinese character corresponds to 1.16 tokens, not 1.6.

3.3.3 Segment-wise Chinese coefficients

Table 4 reports the Chinese coefficient computed independently for each third.

Table 4 – Chinese coefficient per segment

Segment	a_{ch}	Deviation from global (1.16)
Front 1/3	1.18	+0.02
Middle 1/3	1.09	−0.07
Back 1/3	1.20	+0.04

The variation (1.09 – 1.20) is modest, confirming the robustness of the global estimate.

3.3.4 Empirical formula vs. actual token count

Using the common heuristic (Chinese × 1.6, English × 0.25, Digits × 0.5, Other × 0.5) we obtain an *estimated* token total of 1 361 903. The actual token count is 1 077 046, resulting in a bias of −20.9% (i.e., the heuristic overestimates by roughly 210 k tokens).

3.3.5 Byte-per-token analysis

The UTF-8 byte estimate is

$$B = 3 \times 652\,411 + 1 \times 536\,849 + 1 \times 47\,747 + 1.5 \times 319\,920 = 3\,021\,709 \text{ bytes.}$$

Consequently

$$\frac{B}{T} = \frac{3\,021\,709}{1\,077\,046} = \mathbf{2.81} \text{ bytes/token.}$$

This lies below the typical 3.5 – 4.5 bytes/token range reported for natural language. Possible causes are discussed below.

4. Discussion

4.1 Significance of the 1.16 Chinese coefficient

1. BPE merging effect. In the cl100k_base vocabulary many frequent Chinese words (e.g., “人工智能”, “深度学习”) are encoded as a single token. This reduces the average characters-per-token from the naïve 1.6 to roughly 1.16.
2. Implications for the three-layer framework. The L2 semantic-correction layer previously relied on the 1.6 heuristic to estimate token consumption; replacing it with 1.16 yields a ~20% cost reduction in the SNR calculation, making the framework more precise for Chinese-heavy corpora.
3. Broad relevance. Any downstream work that uses tiktoken for budgeting (prompt design, context-window planning, cost estimation) should adopt the empirically derived coefficient when Chinese dominates the input.

4.2 Systematic over-estimation of the empirical formula

The 20.9% over-estimate is not random noise; it stems almost entirely from an inflated Chinese coefficient. The original 1.6 factor likely originates from early English-centric experiments where Chinese characters were treated as three independent bytes, ignoring BPE’s ability to fuse frequent multicharacter tokens. The English, digit, and other coefficients appear accurate, suggesting that correcting only the Chinese factor suffices to eliminate most of the bias.

4.3 Why the average bytes per token is low

Two complementary explanations:

1. High proportion of English/code. English words, numbers and code tokens are single-byte in UTF-8, pulling the average down.
2. Purification pipeline. The cleaning process stripped large blocks of whitespace, HTML tags and indentation—content that is high-byte but low-token. Consequently the remaining corpus is “byte-light”.

A planned follow-up will re-run the analysis on the raw HTML dialogue and on a pure Chinese news corpus to isolate the respective impacts.

4.4 Limitations and future work

Limitation	Planned improvement
Single tokenizer (cl100k_base)	Evaluate additional encodings (p50k_base, o200k_base) and compare coefficients.
Domain-specific data (technical dialogue)	Apply the pipeline to news articles, social-media posts, and literary texts to test cross-domain stability.

Limitation	Planned improvement
Coarse “Other” category	Refine “Other” into punctuation, symbols, whitespace using Unicode blocks; assess impact on $a_{(ot)}$.
Linear-system assumption	Fit a multivariate regression (least-squares) that simultaneously estimates all four coefficients, checking for multicollinearity.
Neglect of emojis / rare symbols	Add explicit counting for emojis and surrogate-pair characters; quantify their token cost.

4.5 Practical take-aways from the three-stage evolution

The middle segment (English share ≈ 44 %, token-ratio 1 : 7.2) is the prime target for any study on long-context memory, retrieval, or knowledge-integration: it holds the densest technical content. Conversely, the final segment (Chinese share ≈ 55 %) is suited for evaluating summarisation, reflection and academic-writing capabilities. Researchers can thus allocate evaluation resources according to the linguistic focus of each stage.

---

5. Conclusion

We performed a large-scale, empirical analysis of the tiktoken compression behaviour on Chinese long text using a purified million-token dialogue corpus. The key outcomes are:

1. Chinese coefficient ≈ 1.16, far below the textbook 1.6, leading to a 20.9 % over-estimation when the heuristic is used.
2. English, digit and other symbols follow the textbook coefficients (0.25, 0.5, 0.5) and can be safely retained.
3. The dialogue displays a clear three-stage evolution (definition → technical-hardship → summarisation) with distinct language-mix patterns.
4. Average bytes/token = 2.81 B, lower than the usual 3.5 – 4.5 B; the discrepancy is attributed to a high proportion of English/code and aggressive data cleaning.
5. Segment-wise Chinese coefficients (1.09 – 1.20) confirm the robustness of the global reverse-engineering result.

Limitations. The study uses a single tokenizer, a single technical-domain corpus, and coarse character categories.

Future work. We will (i) extend the analysis to multiple tokenizers, (ii) test on diverse domains, (iii) adopt finer-grained character classes, (iv) explore raw

(unpurified) corpora, and (v) integrate the corrected coefficients into downstream cost-estimation tools for LLM prompting.

Acknowledgments

We thank the DeepSeek million-token project for providing the full dialogue dataset and the methodological foundation laid by our earlier three-layer quantization framework.
The analysis scripts, environment specifications and a step-by-step replication guide are publicly released at
